**Abstract**

Among all cancers, colorectal cancer is the second leading cause of cancer related death. Liver and lung are known as the main metastatic sites of colorectal cancer, on the other hand the metastasis of adrenal is clinically rare. Formerly, metastases were detected at autopsy, but due to improved imaging and diagnostic techniques, many of these lesions now can be detected on routine follow-up imaging. Patients with adrenal metastasis are considered having systemic spread and therefore unsuitable for surgical resection. That’s why, isolated adrenal metastasis presents a therapeutic dilemma in colorectal cancer patients. In this case, we report an adrenal mass in a patient with colorectal cancer to whom rectosigmoidectomy, colectomy and adrenal metastasectomy were performed. The adrenal mass was benign. For solitary and resectable lesions adrenalectomy can be performed and prolonged survival can be achieved in selected patients. Also, this enables to achieve right histopathological diagnosis.

**Introduction**

Among all cancers, colorectal cancer is the second leading cause of cancer related death. Although the liver and the lung are the main metastatic sites of colorectal cancer, the adrenal metastasis is clinically rare. Adrenal metastases most commonly occur in patients with lung and breast cancer [1, 2]. Generally, metastasis to the adrenal glands are regarded as an indicator of wide spread disease, but in rare cases, isolated adrenal metastasis can also exist [3-5]. However, benign tumours of the adrenal gland such as
pheochromocytoma may cause misdiagnosis in cancer patients so that patients may be misinterpreted as evidence of having metastatic disease. Thus, this is a diagnostic challenge for physician and source of anxiety for the patients [6-8].

Case report
A 55-year-old female was admitted to the hospital with abdominal distension and tenesmus. There was no family history for malignancy.

In physical examination, there was an incision scar. The other examinations were normal. In laboratory findings (Table 1), the tumour was non-functional and carcinoembryonic antigen (CEA) was high. Rectosigmoidoscopy was performed and an ulcerovegetant tumoural mass was found at 15 cm from anal verge. Biopsy was performed. Histopathology of the biopsy specimen showed adenocarcinoma of rectum. For staging, MRI of the abdomen (Figure 1) and PET-CT (Figure 2) were performed. Abdominal MRI detected a tumour of 35x30 mm in the left adrenal gland. PET-CT showed a mass in rectosigmoid junction with a high fluorodeoxy glucose uptake (SUV max: 23.7) and a mass in left adrenal gland (SUV max: 12.0). She applied to Cumhuriyet University in Sivas.

![Figure 1. Magnetic resonance imaging showing a tumour of 35X30mm in the left adrenal gland.](image)
Rectosigmoidectomy, colectomy and adrenal metastasectomy were performed. Her postoperative course was evenful. The histopathologic results of rectum specimen and adrenal mass revealed adenocarcinoma and benign pheochromocytoma respectively. According to the TNM classification the patient had stage 3 tumour. Therefore we applied 8 cycles of adjuvant chemotherapy with FOLFOX-6 (oxaliplatin, 85mg/m²; d1, leucovorin 200mg/m²; d1 5 fluorouracil bolus 400mg/m²; d1 and 2400mg/m² 46 hours-infusion). The patient is still disease-free.

**Discussion**

Although the liver and the lung are the main metastatic sites of CRC, the adrenal metastasis is clinically rare. But in autopsy series, the metastasis ranges are from 1.9% to 17.4 [1, 9]. The rate of detecting clinically silent adrenal masses has increased due to the widespread use of abdominal imaging modalities, including USG, PET-CT, MRI [10-12].

When an adrenal mass is detected in a cancer patient, it is important to determine whether it is a metastasis or not. In these patients, adrenal mass may be a solitary adrenal adenoma, adrenocortical carcinoma or metastasis. An adrenal metastasis in cancer patients is usually found as part of widespread metastasis, but in some cases it occurs as a solitary adrenal metastasis. Currently, isolated adrenal metastasis can be confused with benign adrenal tumours such as adenoma and pheochromocytoma. To identify the adrenal mass is either malign or benign biopsy should be performed. In autopsy studies, the prevalence of incidentaloma is 1-9% [13] and the rate of metastasis ranges from 1.9-17.4% [1, 9]. It is generally accepted that a solitary adrenal metastasis should be resected immediately to achieve good prognosis in some cancer types [14-15]. According to the histopathological diagnosis, chemoregimen might be changed [14].

Laparoscopic adrenalectomy has replaced open adrenalectomy as a procedure of choice for adrenal tumours. However, the efficacy of laparoscopic resection is controversial for large, potentially malignant adrenal tumours. [16]. Therefore it is essential to differentiate benign and non-functional lesions. Isolated adrenal mass should be determined as either benign or malign.

In our case, imaging modalities showed an adrenal metastasis. Therefore the stage of tumour was 4. Rectosigmoidectomy, colectomy and adrenal metastasectomy were performed. The histopathology results showed adenocarcinoma in rectum and benign pheochromocytoma for the adrenal mass.
As a conclusion, isolated adrenal metastasis confuses with benign adrenal tumours such as adenoma and pheochromocytoma. Adrenalectomy for solitary, resectable lesions can be performed and prolonged survival can be achieved in selected patients.
